Background: Transcatheter closure of patent foramen ovale (PFO) has become an effective therapeutic strategy for cryptogenic stroke (CS). The identification of high-risk PFO is essential, but the data are limited. This study aimed to clarify the factors related to CS and to develop a score for high-risk PFO.

Methods: We retrospectively analyzed 57 patients with prior CS and 50 without CS who were scheduled for transcatheter closure. PFO characteristics were evaluated by transesophageal echocardiography. Based on factors related to CS, we estimated the risk score.

Results: Patients with CS had a greater frequency of large-size PFO ($\geq 2 \text{ mm in height}$), long-tunnel PFO ($\geq 10 \text{ mm in length}$), atrial septal aneurysm, hypermobile interatrial septum, prominent Eustachian valve or Chiari’s network, the large right-to-left shunt at rest and during Valsalva maneuver, and low-angle PFO ($\geq 10^\circ$ of PFO angle from inferior vena cava), compared with patients without CS. Multivariate analysis showed that long-tunnel PFO, the presence of hypermobile interatrial septum, the presence of prominent Eustachian valve or Chiari’s network, the large right-to-left shunt during Valsalva maneuver, and low-angle PFO were independently related to CS. When the score was estimated based on 1 point for each factor, the proportion of CS was markedly elevated with a score of $\geq 2$ points. The probability of CS was markedly different between scores of $\leq 1$ or $\geq 2$ points.

Conclusions: PFO risk can be assessed with a score based on high-risk features. The presence of two or more high-risk PFO features is associated with CS. (J Am Soc Echocardiogr 2019;32:811-6.)

Keywords: Cryptogenic stroke, Echocardiography, Patent foramen ovale, Transcatheter closure

Patent foramen ovale (PFO) is linked with various diseases, including cryptogenic stroke (CS) and migraine.\(^1\)\(^6\) The relationship between PFO and CS has become of particular interest, based on recent trials demonstrating that transcatheter PFO closure can reduce the recurrence of stroke compared with medical therapy.\(^7\)\(^9\) The prevalence of PFO is approximately 25% of the general population,\(^10\) but not all PFOs involve CS. As transcatheter closure would be expanded as the therapeutic option, it is important to identify cases of high-risk PFO who are most likely to be associated with CS. However, there are limited data on the comprehensive assessment of PFO morphology associated with the development of CS.\(^11\)\(^12\) This study aimed to compare the anatomical and functional characteristics of PFO using transesophageal echocardiography (TEE) between patients with CS and those without CS and to clarify the factors related to CS. Furthermore, this study aimed to develop a scoring system for the identification of high-risk PFO.

METHODS

Study Population

We retrospectively enrolled 107 consecutive patients with PFO who were scheduled for transcatheter closure for CS or migraine from May 2008 to December 2017. Patients with CS were proven to have cerebral infarction using magnetic resonance imaging. CS was diagnosed by a neurologist based on the exclusion of all other identifiable causes of stroke such as large artery atherosclerosis, cardiogenic embolism, small vessel disease, or arterial dissection after clinical examinations including brain and carotid imaging, electrocardiography, and echocardiography. Patients with CS who were suspected of PFO were referred to our institution to assess for indication of transcatheter closure. All patients underwent TEE to identify the presence of PFO. When PFO was detected and the other causes of CS were excluded, transcatheter closure was scheduled. Migraine was diagnosed according to the criteria of the International Headache Society.\(^13\) Patients
with migraine underwent magnetic resonance imaging and were confirmed to have no cerebral infarct lesion. They were referred to our institution to assess for indication of transcatheter PFO closure. Patients who were detected PFO by TEE were scheduled for transcatheter closure. This study classified patients with migraine as the group of PFO patients without CS. All patients gave written informed consent for the examinations. The study was approved by the ethics committee of our institution.

Echocardiography

TEE was performed for PFO diagnosis before transcatheter closure using iE33 with an X7-2t probe (Philips Medical Systems, Andover, MA) under local anesthesia. Intravenous sedation was administered if needed, although patients remained able to follow instructions for Valsalva maneuver. The presence of PFO was confirmed when

**Figure 1** PFO characteristics. (A) The height of PFO was measured by the maximum separation (arrow). (B) The length of PFO tunnel was measured by the maximum overlap (arrow). (C) The moving and floppy septum was defined as hypermobile interatrial septum. (D) The maximum number of microbubbles was counted. (E) The angle between IVC and PFO was measured. LA, Left atrium; RA, right atrium.
microbubbles crossed from the right to left atrium within three cardiac cycles after opacification of the right atrium, using intravenous injection of agitated saline contrast. The anatomical and functional characteristics of PFO, such as the height of PFO, the length of PFO tunnel, the presence of atrial septal aneurysm (ASA), the presence of hypermobile interatrial septum, the presence of prominent Eustachian valve or Chiari’s network, the grade of right-to-left (RL) shunt at rest and during Valsalva maneuver, and the angle between inferior vena cava (IVC) and PFO, were evaluated by independent cardiologists who were unaware of the CS status of the patient. The height of PFO was measured by the maximum separation between the septum primum and septum secundum in the end-systolic frame (Figure 1A), and a height ≥2 mm was defined as large-size PFO. The length of PFO tunnel was measured by the maximum overlap between the septum primum and septum secundum (Figure 1B), and a length ≥10 mm was defined as long-tunnel PFO. ASA was defined as ≥10 mm of septal excursion from the midline into the right or left atrium or ≥15 mm of total excursion between the right and left atrium. We also defined the moving and floppy septum with ≥5 mm of septal excursion in every heartbeat as hypermobile interatrial septum (Figure 1C). The presence of prominent Eustachian valve was defined as ≥10 mm protrusion within the right atrium. The grade of RL shunt was assessed at rest and during Valsalva maneuver using agitated saline contrast. The maximum number of microbubbles that appeared in the left atrium was counted in a single frame using agitated saline contrast. The maximum number of microbubbles crossed from the right to left atrium within three cardiac cycles after opacification of the right atrium, using intravenous injection of agitated saline contrast. The anatomical and functional characteristics of PFO, such as the height of PFO, the length of PFO tunnel, the presence of atrial septal aneurysm (ASA), the presence of hypermobile interatrial septum, the presence of prominent Eustachian valve or Chiari’s network, the grade of right-to-left (RL) shunt at rest and during Valsalva maneuver, and the angle between inferior vena cava (IVC) and PFO, were evaluated by independent cardiologists who were unaware of the CS status of the patient. The height of PFO was measured by the maximum separation between the septum primum and septum secundum in the end-systolic frame (Figure 1A), and a height ≥2 mm was defined as large-size PFO. The length of PFO tunnel was measured by the maximum overlap between the septum primum and septum secundum (Figure 1B), and a length ≥10 mm was defined as long-tunnel PFO. ASA was defined as ≥10 mm of septal excursion from the midline into the right or left atrium or ≥15 mm of total excursion between the right and left atrium. We also defined the moving and floppy septum with ≥5 mm of septal excursion in every heartbeat as hypermobile interatrial septum (Figure 1C). The presence of prominent Eustachian valve was defined as ≥10 mm protrusion within the right atrium. The grade of RL shunt was assessed at rest and during Valsalva maneuver using agitated saline contrast. The maximum number of microbubbles that appeared in the left atrium was counted in a single frame (Figure 1D), and the large RL shunt was defined as ≥20 microbubbles. We measured the angle between IVC and PFO flap on an imaging plane that displayed the IVC and interatrial septum (Figure 1E), and an angle of the PFO from the IVC ≤10° was defined as low-angle PFO.

Statistical Analysis

Data are presented as mean ± SD for continuous variables and as number and percentage for categorical variables. Differences between the two groups were analyzed by the t-test and Mann-Whitney U-test for continuous variables and the χ²-test for categorical variables. Univariate and multivariate logistic analysis was performed to identify independent factors related to CS. Variables for analysis included large-size PFO, long-tunnel PFO, the presence of hypermobile interatrial septum, the presence of prominent Eustachian valve or Chiari’s network, the large RL shunt during Valsalva maneuver, and low-angle PFO. Odds ratios are shown with 95% CIs. Based on the results of multivariate analysis, the score of high-risk PFO was estimated. Statistical analysis was performed with statistical software (JMP version 11.0; SAS Institute, Cary, NC), and significance was defined as a value of P < 0.05.

Inter- and intraobserver differences were analyzed in 20 randomly selected images. The length of PFO tunnel, the presence of hyper-mobile interatrial septum, and the large RL shunt during Valsalva maneuver were evaluated by two blinded observers and by a single observer at two different times. Reliability was calculated by Pearson’s correlation coefficient. Variability was calculated as the percentage error of each measurement and derived as the difference between the two measurements divided by the mean value.

RESULTS

Patient Characteristics

The mean age of all patients was 45 ± 15 years. Comparisons of patient characteristics between 57 patients with CS and 50 without CS are shown in Table 1. Patients with CS were older than those without CS. The prevalence of hypertension was higher in patients with CS than in those without CS.

Echocardiographic Characteristics of PFO

Comparisons of the anatomical and functional characteristics of PFO between the two groups are shown in Table 2. The height of PFO was greater in patients with CS than in those without CS, and large-size

Data are presented as mean ± SD or n (%) of patients.
PFO (≥2 mm) was more frequently observed in patients with CS. While long-tunnel PFO (≥10 mm) was more frequently observed in patients with CS than in those without CS, there was no difference in the mean length of PFO tunnel between the two groups. This was because short-tunnel PFO (≤2 mm) was also frequent in patients with CS. Patients with CS more frequently had ASA, hypermobile interatrial septum, and prominent Eustachian valve or Chiari’s network compared with those without CS. The large RL shunt at rest and during Valsalva maneuver was more frequently observed in patients with CS than in those without CS. The angle between IVC and PFO was lower in patients with CS than in those without CS, and low-angle PFO (≤10°) was more frequently observed in patients with CS.

Factors Related to CS
Multivariate logistic analysis showed that long-tunnel PFO, the presence of hypermobile interatrial septum, the presence of prominent Eustachian valve or Chiari’s network, the large RL shunt during Valsalva maneuver, and low-angle PFO. Variables for multivariate analysis 2 added age and the prevalence of hypertension.

High-Risk PFO Score
By scoring each independent factor related to CS as 1 point (Table 4), we estimated the score of high-risk PFO. The proportion of patients with CS and those without CS according to the score is shown in Figure 2. The proportion of CS was 5% or 17% at a score of 0 or 1 point, respectively. However, the proportion of CS was markedly elevated at a score of ≥2 points, with 80%, 87%, or 89% at a score of 2, 3, or 4 points, respectively. The probability of CS was also markedly different between scores of ≤1 or ≥2 points. A score of 2 points had 91% sensitivity and 80% specificity for the association with CS. The false-positive rate and the false-negative rate were 20% and 9%, respectively. Among patients with CS who had a score of ≥2 points, the individual components related to CS are shown in Figure 3. The presence of hypermobile interatrial septum and the large RL shunt during Valsalva maneuver were strongly related to CS.

Reproducibility
There was good agreement in the measurements of the length of PFO tunnel between the two blinded observers ($r = 0.98$, $P < .001$) and for the intraobserver ($r = 0.97$, $P < .001$). The inter- and intraobserver variabilities for the length of PFO tunnel were 4.8% and 5.1%, respectively. There was 100% agreement in the classification of the hypermobile interatrial septum and also the large RL shunt during Valsalva maneuver by both of the blinded observers and a single observer assessing twice.

DISCUSSION
The present study evaluated the anatomical and functional characteristics of PFO in patients with CS and those without CS. The major findings were as follows: (1) long-tunnel PFO, the presence of hypermobile interatrial septum, the presence of prominent Eustachian valve or Chiari’s network, the large RL shunt during Valsalva maneuver, and low-angle PFO were independent factors related to CS; and (2) PFO with a score ≥2 points was associated with CS when
Factors Related to CS

Because transcatheter PFO closure has recently become an effective therapy for stroke, accurate diagnosis of PFO is needed.25,26 Furthermore, it is essential to stratify PFO for an increased risk of CS. Previous studies have reported that the large-size PFO, the large RL shunt, and the presence of ASA were risk factors for an increased likelihood that PFO was causally linked to CS.11,18-20 The presence of prominent Eustachian valve or Chiari’s network was also related to CS in this study. The Eustachian valve is an embryological remnant of the valve that prenatally directs blood flow from the IVC to fossa ovalis of the septum. Chiari’s network is a mobile structure that extends from the junction of the IVC and right atrium to the septum. Both structures can direct IVC blood flow through PFO and predispose to CS. The mechanism of CS may also relate to the angle between the IVC and PFO. Indeed, we provide new evidence that the low angle between the IVC and PFO is related to CS. The low angle may preferentially direct IVC blood flow toward the interatrial septum and PFO orifice. Similar to the previous study,11 this study showed that long-tunnel PFO was related to CS. The septal pouch on the left side of interatrial septum was reported to be associated with CS caused by thrombus formation.24 Long-tunnel PFO might also be the site for thrombus formation because of turbulent and stagnant blood flow.11 In contrast, patients with CS have also been reported to have short-tunnel PFO.25 Thus, further studies are required to elucidate the relationship between the length of PFO tunnel and CS and to identify the mechanisms.

Clinical Implications

Recent randomized trials demonstrated the benefits of transcatheter closure for the reduction of stroke compared with medical therapy,7-9 although the earlier trials such as CLOSURE I, PC, and RESPECT failed to show the superiority.26-28 These discrepancies between the earlier negative trials and recent positive trials are thought to relate to patient selection for transcatheter PFO closure. Because PFO is a frequent finding,10 the identification of high-risk PFO is important. There are likely multiple factors involved in the role of PFO in causing CS. Thus, the scoring system using these factors may be useful for clinical stratification of PFO. In the present study, we developed a scoring system for the identification of high-risk PFO associated with CS, with each factor related to CS scored as 1 point. The association with CS was low at a score of 0 or 1 point, but it was markedly elevated at a score of ≥2 points. Indeed, at a score of ≥2 points, the sensitivity and the specificity for the association of PFO with CS were 91% and 80%, respectively. These findings suggest that a score of ≥2 points is clinically useful for stratifying PFO for risk of developing of CS and thus for selection of appropriate patients for PFO closure.

Study Limitations

There are several limitations to the present study. First, this was a retrospective cohort study. Thus, the score was not assessed to predict who will develop a CS. Second, there was selection bias because only patients who were scheduled for transcatheter PFO closure were selected. Therefore, our study population had a high proportion of high-risk subjects and was not representative of the general population.
population with PFO. A larger study including patients who were not considered for transcatheter closure is required to confirm our findings. Third, neurologically asymptomatic subjects who had a PFO on TEE would be the ideal control or comparison group, but for this study we used patients with migrane as the control group. Fourth, the grade of RL shunt might be underestimated because it depends on the degree of Valsalva maneuver. However, the TEE and Valsalva assessment were performed uniformly by the operators at our institution. Lastly, the number of cases may be too small to determine in the multivariate analysis whether certain components in the score should have different weights.

CONCLUSION

Long-tunnel PFO, the presence of hypermobile interatrial septum, the presence of prominent Eustachian valve or Chiari’s network, the large RL shunt during Valsalva maneuver, and low-angle PFO were related to CS. When two or more of these features are present on TEE, there is a strong association with CS. Thus, a score that accounts for the presence of these PFO features may be valuable for identifying patients with PFO at high risk of CS.
